Foreign body impaction in the sigmoid colon: A twenty euro bet

Katalin E Müller, András Arató, Péter László Lakatos, Mária Papp, Gábor Veres

INTRODUCTION

Foreign body ingestion is a common problem in everyday emergency practice, primarily in children. Fortunately, the majority of the ingested foreign objects pass through the gastrointestinal tract without complications. Foreign body ingestion may present without symptoms[1], and in some cases results in perforation with gastrointestinal bleeding or an obstruction[1]. Rarely, an abscess or a fistula occurs[1]. It has been reported to mimic other diseases (renal stone or irritable bowel syndrome)[1]; however, there are no literature data concerning differential diagnostic difficulties of Crohn’s disease (CD) and a foreign body.

CD is a chronic relapsing inflammatory gastrointestinal disease. It is often difficult to diagnose due to the fact that there is no single pathognomonic sign or symptom. Here we report on a case with chronic abdominal symptoms, weight loss and occult bleeding suggesting CD. However, at colonoscopy, a swallowed pen was impacted in the sigmoid region causing the aforementioned symptoms.

CASE REPORT

A thirteen-year-old boy was admitted to the First De-
partment of Paediatrics at Semmelweis University with 10-kg weight loss in the last 6 mo and intermittent colicky abdominal pain. Past medical history revealed that 6 mo previously he was admitted to hospital for 2 d due to acute abdominal pain and vomiting. He was given intravenous fluids and his complaints improved. However, anorexia persisted, abdominal pain returned intermittently, and he lost 10 kg during this period. Stool blood test was positive twice, while stool culture, parasite and assays for *Clostridium difficile* toxins A and B were all negative. Considering the age of the patient, weight loss, chronic abdominal pain and positive stool blood test, as well as negative stool culture, inflammatory bowel disease was suspected and he was referred to our clinic.

Physical examination revealed normal vital signs without any clinical abnormalities. His abdomen was soft, non-tender, without guarding or palpable masses. There was normal sphincter tone, no perianal abscess, skin tag or fistula at rectal examination. Laboratory tests showed normal red blood cell count, white blood cell count and thrombocyte count. C-reactive protein, total protein and albumin were within the normal limits. Abdominal ultrasound showed slight wall thickening in the descending colon. There was no family history of inflammatory bowel disease.

The upper endoscopy was negative. There were no ulcers, no sign of bleeding, and no antral or bulbar lymphonodular hyperplasia. The terminal ileum and the colon appeared normal, confirmed by multiple mucosal biopsies at histology. Surprisingly, at withdrawal of the colonoscope, an impacted foreign body (plastic half-ball pen, Figure 1) was observed embedded in the sigmoid region. The surrounding mucosa was inflamed, with no visible mucosal vessels. The plastic, numbered ballpoint pen could not be removed by Dormia set and polypectomy snare despite several attempts. After the diagnostic procedures, the patient admitted swallowing a half-plastic pen as a 20-euro bet with his friend 6 mo ago. At first, he thought there might have been a connection between the swallowed pen and his symptoms as he had a hospital admission for 2 d due to acute abdominal pain and vomiting (see above). Later, he was embarrassed and hoped that these two events were just a coincidence. He never disclosed his bet.

Plain abdominal X-ray and abdominal ultrasound were performed the next day after endoscopy, but the foreign body could not be visualized. The pen passed through the colon spontaneously hence the control colonoscopy showed no foreign body after 5 d. The patient had no symptoms during 21 mo of follow-up; his weight gain is normal, and there is no occult bleeding.

**DISCUSSION**

We report on a case of an ingested foreign body as a twenty-euro bet. To our knowledge, this is the first description of a swallowed object causing chronic gastrointestinal symptoms in a pediatric patient. However, ingested foreign bodies are a common event in the pediatric population.

The first recorded pediatric foreign body ingestion was described by Frederick the Great in 1692[2]. Most accidentally ingested foreign bodies go undetected and pass through without any incident. However, 10% to 20% require endoscopic removal and 1% or less require surgical intervention[1]. In general, the passing of an ingested foreign body depends on the anatomic conditions of the gastrointestinal tract and on factors related to the ingested foreign body. Long, thin objects as seen in our case are less likely to pass the pylorus or the duodenum[2]. The presenting features vary according to the site and include pancreatitis, hepatic abscess, appendicitis, intussusceptions and irritable bowel syndrome[1-3].

There are only a few reports of foreign bodies mimicking CD in the English literature. Ioannidis et al[4] reported on a case of incidental toothpick ingestion which caused an ileum fistula and mimicked CD. In addition, a patient presented with recurrent, subacute obstruction and right iliac mass mimicking the presentation of CD[5]. Subsequent lower endoscopy revealed small bowel phytobezoar which passed spontaneously.

To our knowledge, only one pediatric case of an ingested foreign body mimicking CD has been reported[6]; nevertheless, this was an acute event. A 7-year-old boy presented with a 2-wk history of cramping abdominal pain and low grade fever. Colonoscopy revealed an oedematous, friable rectosigmoid junction with a solitary fistula or ulcer. Hydrocortisone enemas were prescribed with minimal improvement. Seven days later his condition became more serious, and a computed tomography scan revealed a right iliopsoas abscess. Repeated colonoscopy showed a toothpick in the lumen of the rectosigmoid colon.

Foreign bodies usually cause acute symptoms of perforation, obstruction or gastrointestinal bleeding. However, our patient had chronic symptoms. This is probably due to the lack of perforation or obstruction. Meanwhile, his symptoms were similar to the reported cases, in which perforation or fistula was diagnosed.

We were presented with a healthy, young adolescent with chronic abdominal pain, weight loss and occult bleeding - classic presenting features of pediatric inflam-
matory bowel disease. Our working hypothesis was CD, though the laboratory tests were negative. Colonoscopy revealed a plastic, half-ball pen embedded in the sigmoid mucosa. The patient concealed swallowing a half-pen as a 20-euro bet with his friend. His subsequent hospital admission due to vomiting and acute abdominal symptoms may be explained as due to gastric irritation. Later the foreign body passed through the upper gastrointestinal tract and impacted in the sigmoid region. We speculate that occult bleeding was caused by the chronic mucosal irritation around the embedded pen. Anorexia and abdominal pain can be explained by the increased bowel peristalsis around the logged pen\textsuperscript{7}.

The value of imaging studies for an ingested foreign body seems to be questionable based on our case. Hence, plain abdominal X-ray (plastic pen) and abdominal ultrasound (sigmoid localization) could not identify the pen. Nevertheless, the role of imaging studies is crucial to determine the inflammatory reaction in and around the bowel wall and to exclude findings requiring surgical intervention\textsuperscript{7}.

The majority of ingested foreign bodies that reach the stomach pass through the alimentary tract without complication. If not, the management of ingested foreign bodies is dependent on their size, shape, material and location. After imaging studies, endoscopy should be considered as the crucial step in management since it is a potent and safe diagnostic tool. On the other hand, surgical treatment is mandatory in the presence of complications such as abscesses and fistulas\textsuperscript{7}. In our patient, we attempted the removal of the embedded pen, but due to the increased possibility of perforation, we did not prevail. Subsequently, the pen was spontaneously passed after the first endoscopy as a result of the previous attempts of removal.

In summary, we report on an adolescent patient with chronic gastrointestinal symptoms due to a swallowed plastic pen that mimicked CD. Therefore, an ingested foreign body should be included in the differential diagnostic procedure related to chronic gastrointestinal symptoms.
